ABSTRACT

Family with sequence similarity (FAM46) proteins are newly identified metazoan-specific poly(A) polymerases (PAPs). Although predicted as Gld-2-like eukaryotic non-canonical PAPs, the detailed architecture of FAM46 proteins is still unclear. Exact biological functions for most of FAM46 proteins also remain largely unknown. Here, we report the first crystal structure of a FAM46 protein, FAM46B. FAM46B is composed of a prominently larger N-terminal catalytic domain as compared to known eukaryotic PAPs, and a C-terminal helical domain. FAM46B resembles prokaryotic PAP/CCA-adding enzymes in overall folding as well as certain inter-domain connections, which distinguishes FAM46B from other eukaryotic non-canonical PAPs. Biochemical analysis reveals that FAM46B is an active PAP, and prefers adenosine-rich substrate RNAs. FAM46B is uniquely and highly expressed in human pre-implantation em-bryos and pluripotent stem cells, but sharply down-regulated following differentiation. FAM46B is localized to both cell nucleus and cytosol, and is indispensable for the viability of human embryonic stem cells. Knock-out of *FAM46B* is lethal. Knock-down of FAM46B induces apoptosis and restricts protein synthesis. The identification of the bacterial-like FAM46B, as a pluripotent stem cell-specific PAP involved in the maintenance of translational efficiency, provides important clues for further functional studies of this PAP in the early embryonic development of high eukaryotes.

INTRODUCTION

PAPs are a branch of the nucleotidyltransferase (NTase) superfamily ([1]). Previous structural studies have established close relationship between PAPs and CCA-adding enzymes, another group of template-independent RNA polymerase ([2]). Eukaryotic PAPs share sequence similarity to the class-I archaeal CCA-adding enzymes, whereas bacterial PAPs are

---

homologous to the class-II eukaryotic and bacterial CCA-adding enzymes (3). Eukaryotic PAPs can be classified into two subgroups. The 'canonical' PAPs, represented by nuclear PAPα, are responsible for adding long poly(A) tail during mRNA maturation. They are composed of three domains: an N-terminal catalytic domain containing the signature NTase motif, a central domain and a C-terminal RNA-binding domain (RBD). The 'non-canonical' PAPs, including but not limited to Gld-2, terminal uridylyltransferase (TUTs) and mitochondrial (mt-)PAP, add poly(A) tails or short terminal tails to a variety of RNA substrates including mRNA, snRNA, miRNA, aberrant rRNA and snoRNA (4). Given the diversity of their substrate preference, these non-canonical PAPs are recently renamed terminal nucleotididyltranferase (TENTs) (5). TENTs usually share a bipartite core PAP domain that lacks the RBD, and have different accessory domains to fulfil their diverse functions (4).

Most of the known eukaryotic PAPs are localized in the nucleus, and their activity and specificity relies on the association with other co-factors. For example, PAPα functions as a component of the cleavage and polyadenylation specificity factor (CPSF) complex (6). *Caenorhabditis elegans* (ce)Gld-2 separately forms complex with Gld-3 or RNP-8 to control gamete sex (7). In contrast, bacterial PAPs polyadenylate mRNAs in a non-discriminative manner, and usually require no partner (8,9). In terms of overall structure, bacterial PAPs are characterized by a seahorse-like shape, where the catalytic head domain is linearly aligned with the neck, body and tail domains involved in substrate RNA binding (9). This domain organization is distinct from that of eukaryotic PAPs.

Family with sequence similarity 46 (FAM46) is a group of predicted NTases found mainly in vertebrates (1). Human and mice both have four FAM46 proteins: namely FAM46A/B/C/D (also named TENT5A/B/C/D) (10). The amino acid sequences of these homologs share >40% overall sequence identity, but are not apparently associated with other protein families. Prior bioinformatics analysis suggested that the FAM46 proteins are non-classical PAPs (11), which was supported by a recent study on FAM46C, a putative suppressor for multiple myeloma (12). However, the detailed biological roles of other FAM46 proteins and the structural feature of this protein family still remain unclear.

Most eukaryotic mRNAs carry poly(A) tails, whose length is closely coupled with translational efficiency and mRNA stability (13). These tails are firstly added by nuclear PAPs during transcription termination, and usually shortened by deadenylases (14,15). The poly(A) tails can also be re-extended in the cytoplasm, which may promote translation and inhibit decay of certain mRNAs (16–18). This tail-length regulatory mechanism is considered to be an important regime of translation control in the early development of metazoan (19,20). A cytoplasmic PAP, Gld-2, was found to be responsible for this process during gametogenesis in *C. elegans* (21), *Drosophila* (22) and *Xenopus* (23). However, the cytoplasmic polyadenylation process is less understood in mammalian early embryos, partly due to the lack of information on corresponding PAPs.

In this study, we started from structure determination and revealed that FAM46B is a robust bacterial-like PAP. Being specifically expressed in human pluripotent stem cells, FAM46B is critical for cell viability, possibly by maintaining the stability of certain mRNAs. These results expand the knowledge of eukaryotic PAPs, and provide new insight into the translational control in early development of mammals.

MATERIALS AND METHODS

Protein expression and purification

The cDNAs of *Xenopus tropicalis* (xt), *Homo sapiens* (hs)FAM46B and *Thermotoga maritima* CCA adding enzyme (tmCCA) were purchased from YouBio. All constructs and mutants were expressed from a modified pET28 vector with an N-terminal His$_6$-tag fusion followed by a PreScission protease (PSP) cleavage site. Recombinant plasmids were transformed into *Escherichia coli Rosetta* (DE3) cells. Transformed bacteria were cultured at 37°C in Terrific Broth (TB) medium until OD$_{600}$ reached 0.6, and then induced with 0.1 mM isopropyl-1-thio-β-D-thiogalactopyranoside (IPTG). Induced bacteria were grown overnight at 18°C. Cells were lysed in 50 mM HEPES pH 7.5, 500 mM NaCl, 30 mM imidazole, 5 mM MgCl$_2$, 5 mM KCl, 1 mM phenylmethanesulfonylfluoride (PMSF), 1 μM DNase I and 2 mM β-mercaptoethanol (β-ME) using a cell disruptor (JNBIO) and subjected to centrifugation at 40 000g for 1 h. The supernatant was filtered and applied to a Ni-NTA (first Ni-NTA) column (GE Healthcare) equilibrated with binding buffer A containing 20 mM HEPES pH 7.5, 500 mM NaCl, 30 mM imidazole, 2 mM MgCl$_2$, 2 mM KCl and 2 mM β-ME. The column was extensively washed with buffer A and shortly with 20 mM HEPES pH 7.5, 500 mM NaCl, 70 mM imidazole, 2 mM MgCl$_2$, 2 mM KCl and 2 mM β-ME. Proteins were eluted with 20 mM HEPES pH 7.5, 500 mM NaCl, 300 mM imidazole, 2 mM MgCl$_2$, 2 mM KCl and 2 mM β-ME before incubated with 20 μg glutathione S-transferase (GST)-fused PSP to remove the His$_6$-tag and dialyzed overnight against binding buffer B containing 20 mM HEPES pH 7.5, 300 mM NaCl, 2 mM MgCl$_2$, 2 mM KCl and 2 mM β-ME. After dialysis, PSP was removed using a GST column. The protein was re-applied to a second Ni-NTA column equilibrated with binding buffer B, and eluted with binding buffer A. Eluted proteins were concentrated and loaded onto a HiLoad 16/60 Superdex 200 column (GE Healthcare) equilibrated with gel filtration buffer containing 20 mM HEPES pH 7.5, 150 mM NaCl, 2 mM MgCl$_2$, 2 mM KCl and 1 mM dithiothreitol (DTT). Peak fractions corresponding to monomeric FAM46B were collected. tmCCA was purified as previously described (24), plus an extra ion-exchange step using a Resource Q column (GE Healthcare) to remove the nucleic acids bound to the protein. Cell lysis and protein purification were performed at 4°C.

Crystallization and structure determination

Crystals of xtFAM46B were obtained via hanging vapor diffusion by mixing 10 mg ml^{-1} protein with equal volume

of reservoir solution containing 2% tacsimate pH 5.0, 0.15 M sodium citrate tribasic dehydrate pH 5.6 and 10% PEG 3350 at 10°C. During flash-cooling of the crystals in liquid N_2, a cryo-solution containing 0.15 M sodium citrate tribasic dehydrate pH 5.6, 15% (w/v) PEG3350 and 10% glycerol was used. Diffraction datasets were collected at beamline BL19U1 of the Shanghai Synchrotron Radiation Facility (SSRF) and processed using the XDS suite (25). Phases were solved by molecular replacement using MolRep (26) with the atomic coordinate of mouse FAM46C (will be reported elsewhere) as search model. The structural model was built using COOT (27) and refined with Refmac5 (28) and Phenix (29). Structural validation was carried out using MolProbity (30). Structural illustrations were prepared using the PyMOL Molecular Graphics Systems (version 1.7.0.0, Schrödinger LLC; http://www.pymol.org/). Data collection and refinement statistics can be found in Table 1.

In vitro CCA-adding assay

Truncated tRNAs (mini-tRNAs) with various three-termini were used to substitute full-length immature and mature tRNAs in the *in vitro* CCA-adding assay according to a previous study (31). The mini-tRNAs (mini-tRNA-D, mini-tRNA-DC and mini-tRNA-DCC), each conjugated with a 5′ biotin label, were purchased from Bioneer. For testing AMP/CMP incorporation, 10 μM FAM46B/C or tmCCA was incubated with 10 μM mini-tRNA and 200 μM ATP and/or CTP in a buffer containing 20 mM HEPES pH 7.5, 150 mM NaCl, 4 mM $MgCl_2$ and 4 mM KCl at 37°C for

50 min before analyzed by 22% urea-PAGE. The biotinylated RNA substrates and products were incubated with HRP-conjugated streptavidin and visualized by chemiluminescence using the Chemiluminescent Nucleic Acid Detection Module Kit (Thermo Scientific) according to manufacturer's protocol. All experiments were repeated at least twice and the data showed satisfying consistency.

NTP consumption assay

16 μM protein was incubated with 80 μM A_{15} primer and 80 μM NTP in a buffer containing 20 mM HEPES pH 7.5, 150 mM NaCl, 4 mM $MgCl_2$ and 4 mM KCl at 37°C for 20 min. The mixture was then analyzed by an HPLC system (Agilent) equipped with a reverse phase C18 ODS-2 Hypersil analytical column preceded by a C18 guard column (Thermo Scientific), with 100 mM potassium phosphate pH 6.5, 10 mM tetrabutyl ammonium bromide and 7.5% acetonitrile as running buffer. Nucleotides were detected by absorption at 254 nm and quantified by integration of the corresponding peaks.

NMP incorporation assay

10 μM protein was incubated with 10 μM 5′-biotinylated 15-mer RNA primer (Bioneer) and 200 μM NTP in a buffer containing 20 mM HEPES pH 7.5, 150 mM NaCl, 4 mM $MgCl_2$ and 4 mM KCl at 37°C for 50 min. The mixtures were subjected to 20% urea–PAGE and the biotinylated RNA substrates and products were visualized by Chemiluminescence. All experiments were repeated at least twice and the data showed satisfying consistency.

Polyadenylation assay

10 μM protein was incubated with 5 μM 15-mer RNA primer, 500 μM ATP and 1 ul 1:1000 diluted $[\alpha\text{-}^{32}P]$-ATP (3000 Ci/mmol, PerkinElmer) at 37°C for 50 min. The mixtures were subjected to 20% urea–PAGE. The low range RNA marker (NEB) was pre-labeled with $[\gamma\text{-}^{32}P]$-ATP (3000 Ci/mmol, PerkinElmer) using T4 polynucleotide kinase (NEB). The gels were dried, exposed to a phosphorimaging plate, and scanned using a Typhoon phosphorimager (GE Healthcare). All experiments were repeated at least twice and the data showed satisfying consistency.

Nucleotide binding assay

Binding of xtFAM46B to different adenosine nucleotides were analyzed by using isothermal titration calorimetry (ITC) at 25°C in the buffer containing 20 mM HEPES pH 7.5, 150 mM NaCl, 4 mM $MgCl_2$ and 4 mM KCl. 100 μM protein was titrated by 1 mM adenosine nucleotides with 20 injections, 2 μl each. Resulting heat changes upon each injection was integrated using the PEAQ-ITC program provided by the manufacturer.

In vitro A-tailing experiment

Independent triplicate experiments were performed by incubating 5 μM FAM46B with 5 μM 15-mer random

RNA (N_{15} RNA oligos, Integrated DNA Technologies) in a buffer containing 20 mM HEPES pH 7.5, 150 mM NaCl, 4 mM $MgCl_2$ and 4 mM KCl at 37°C for 50 min. After incubation, samples were extracted with acid-phenol-chloroform pH 4.5 (Thermo Scientific), washed twice with 80% ethanol and eluted into ddH_2O before subjected to 12% urea-PAGE. The poly(A)-added and poly(A) non-added RNA fragments were separated, individually pooled and extracted for preparing sequencing libraries with TruSeq small RNA library preparation kit (Illumina). Sequencing was performed on a Hiseq 2000 platform (Illumina) with 1×50 nt format.

Data analysis for *in vitro* A-tailing experiment

For all reads from the sequencing data, the first 15 bases were sub-stringed, and the index of the first 3 bases 'TGG' of the adapter was searched. The numbers of added A were calculated as 'the index number—15', if 90% of the bases were A between the first 15 bases and the adapter. If no adapter was found and 90% of the bases were A after the first 15 bases, then the number of A equals to 35. Reads without added A (0A) were classed as background, whereas reads with 5A or greater were classed as foreground. The frequencies of ATCG at each position were calculated both in background and foreground. At a particular position j, of a sequence in foreground, $p = (pA, pC, pG, pT)$ denoted the probabilities of the four elements, and $q = (qA, qC, qG, qT)$ denoted the corresponding background probabilities. Defining $r = (rA, rC, rG, rT)$ by: $r_i = p_i/q_i$ ($i = $ A, C, G, T), the sequence logos were drawn using this metric at each position at axis with ggseqlogo software (32).

Phylogenetic analysis

All protein sequences were downloaded from UniProt (https://www.uniprot.org/) and aligned by using MAFFT (https://www.ebi.ac.uk/Tools/msa/mafft/). Phylogenetic tree of whole protein sequence was constructed by using Bayesian Evolutionary Analysis Sampling Trees (BEAST) program, version 1.8.4. Each protein sequence data set was analyzed with the Blosum62 model, strict molecular clock model and coalescent constant size. Sampling and convergence of the runs were evaluated using the Tracer program, version 1.6 (http://beast.community/tracer) until effective sample size values exceeded 200 to ensure sufficient level of sampling. The length of Bayesian Monte Carlo Markov Chain (MCMC) was set 10 000 000, and sampled every 1000. States (the first 10%) were removed as burn-in. Maximum clade credibility trees were visualized with the FigTree program, version1.4.3 (http://beast.community/figtree) and iTOL (https://itol.embl.de/).

Bioinformatics analysis

The RNA-seq reads from published samples were mapped by the STAR mapper (33). The number of uniquely mapped reads was calculated on each annotated gene, and further normalized to fragment per kilobase per million (FPKM) by total number of uniquely mapped reads. For part of the ChIP-seq analysis, the raw sequencing reads of H3K4me3,

H3K27me3 and H3K27ac in H9 hESCs (34) were mapped by bowtie 2 (35) with default parameter settings and MACS2 software was further used for the peak calling. The raw sequencing reads from OCT4, NANOG and SOX2 ChIP-seq data in HUES64 hESCs (36) were mapped to human genome (hg19) by bowtie 2 with default parameter settings, and MACS2 software (37) was further used for the peak calling. Graphics (for bioinformatics analyses) were done in R (http://www.r-project.org/), and ggplot2 (http://ggplot2.org/) was used for part of the graph preparation. The ChIP-seq peaks were visualized in IGV.

Microarray

Three replicates from differentiating hESCs during mesendodermal differentiation were used for RNA extraction. Quality-assessed RNA samples were hybridized to Affymetrix Gene Chip Human Gene 1.0 ST arrays (Affymetrix). Twelve raw data files generated from the Affymetrix scanner passed data quality control and were further performed with RNA normalization through the Affymetrix expression console. Further analysis was performed using SAM (significance analysis of microarrays) software (38).

hESC maintenance and mesendoderm induction

hESCs (H1 [Wi Cell Research Institute]) were maintained in mTeSR1 media (Stem Cell Technologies) on Matrigel (hESC qualified; Corning) coated dishes. For mesendoderm induction, media were changed from mTeSR1 to chemically defined medium (CDM) supplemented with Activin A (R&D Systems), BMP4 (bone morphogenetic protein 4, R&D Systems), bFGF (basic fibroblast growth factor, Invitrogen) and LY294002 (phosphoinositide-3-kinase/AKT serine/threonine kinase inhibitor, Sigma) at approximately 70% to 80% confluency (39,40).

In vitro differentiation assay

Embryoid body (EB) formation was performed as described previously (41). Briefly, hESCs were cultured on matrigel-coated six-well plates. Cells from one well were dissociated with collagenase IV (1 mg ml^{-1}) for 5 min, and then split into small cell clumps. The small cell clumps were transferred into three wells of low-attachment six-well plate, and cultured in EB medium (knock-out DMEM, 20% knock-out serum replacement, 1 mM L-glutamine, 1% nonessential amino acids, 0.1 mM 2-mercaptoethanol and primocin). The medium was changed every 2 days. The embryoid bodies were cultured for 8 days followed by collection for qRT-PCR.

siRNA Transfection

Plates of 12-well (Corning) were coated with 400 µl of diluted Matrigel before addition of siRNA oligos. siRNAs (Qiagen) mixed with Opti-MEM I (GIBCO) were added into the wells. For higher transfection efficiency, a mixture of 2 µl DharmaFect1 (Dharmacon) transfection reagent with 98 µl Opti-MEM I was added into each well after

siRNA addition. After incubation for ∼30 min at room temperature, single cell suspension of 2×10^6 hESCs in 800 μl of mTeSR1 with 10 μM Y-27632 (Stem Cell Technologies) was seeded into each well. 18 h later, Y-27632 was washed off. The working concentration of siRNA was 100 nM. Six hours after washing off Y-27632, RNA samples were collected for further assays unless specified. The siRNA sense sequences are: 5′-UAAGGCUAUGAA GAGAUAC (scramble), 5′-GGCGCCAUUUGUCUUGGA AUU (siRNA-1), 5′-CCGUGUGCCUCAUGAACCAUU (siRNA-2).

Western blot

Experiments were performed as described (42). Briefly, cells were lysed in lysis buffer and cell lysate containing 30 μg protein was used for Western blots. Membranes were incubated with the primary antibody against EOMES (Cat No. ab23345, Abcam, 1:1000), FAM46B (Cat No. 23149-1-AP, Proteintech, 1:1000), GAPDH (Cat No. sc-47724, Santa Cruz Biotechnology, 1:5000), β-Tubulin (Cat No. 30303ES50, YEASEN, 1:1000) and Laimin B1 (Cat No. 16048, Abcam, 1:1000). The membranes were then incubated with IRDye 680LT Donkey anti-Rabbit IgG (Cat No. 926-68023, Li-COR Biosciences) or IRDye 800CW Donkey anti-Mouse IgG (Cat No. 926-32212, Li-COR Biosciences) as secondary antibodies and visualized on an Odyssey Infrared Imager (Li-COR Biosciences).

CRISPR knock-in

To generate hESCs with the $3 \times$ Flag-tagged FAM46B, a two-step strategy was adopted, including (i) integration of PGK-Puro-IS-$3 \times$ Flag in the 5′ flanking region of the start codon, and (ii) excision of the sequence between TTAA by using an excision-only PiggyBac Transposase PBx, leaving behind $3 \times$ Flag sequence linked to the start codon of FAM46B. Single clones were selected and one clone of the hESCs with Flag-tagged FAM46B protein was confirmed by sequencing and Western blot analysis.

Immunocytochemical staining

Immunofluorescence assay was performed according to the protocol described previously (43). Briefly, the attached cells were harvested at indicated stages, fixed with 4% paraformaldehyde, permeabilized in 0.4% Triton X-100 (Sigma-Aldrich) for intracellular antigens, blocked in 10% normal goat serum (Vector Laboratories), and then stained with antibodies to FAM46B (Cat No. 23149-1-AP, Proteintech, 1:200). Antibody labeling was visualized using DyLight 488-conjugated secondary antibodies (all from Jackson ImmunoResearch Laboratories, 1:1000). Nuclei were counterstained with Hoechst 33258 (Sigma-Aldrich, 1:2000). A Zeiss Observer microscope was used for slide observation and image capture.

qRT-PCR

Total RNA was prepared using the RNAprep pure Micro Kit (TIANGEN) following the manufacturer's instructions. cDNAs were generated by reverse-transcribed total RNA (1 μg) using ReverTra Ace reverse transcriptase (Toyobo). qRT-PCR was performed and analyzed by the ViiA™ 7 Real-Time PCR System (Life Technologies) with SYBR Green qPCR Master Mix (Roche). The qRT-PCR data were shown as fold changes normalized to internal control PBGD. The qRT-PCR primers are listed as follows:

Gene	Primer sequence (5′-3′)	AT (°C)	PS (bp)
FAM46B	F-CCTGCCTACTAGACTTCCTGC R-CTTGCCGCTCTTGTTGGACA	60	149
OCT4	F-AGTGAGAGGCAACCTGGAGA R-ACACTCGGACCACATCCTTC	60	81
NANOG	F-CATGAGTGTGGATCCAGCTTG R-CCTGAATAAGCAGATCCATGG	60	191
SOX2	F-GGGAAATGGGAGGGGTGCAA AAGAGG R-TTGCGTGAGTGTGGATGGGA TTGTG	60	151
PBGD	F-ATTACCCCGGGGAGACTGAAC R-GGCTGTTGCTTGGACTTCTC	60	130
SOX1	F-ACCAGGCCATGGATGAAG R-CTTAATTGCTGGGGAATTGG	60	67
GATA4	F-GGAAGCCCAAGAACCTGAAT R-GTTGCTGGAGTTGCTGGAA	60	98
T	F-ACCCAGTTCATAGCGGTGAC R-CCATTGGGAGTACCCAGGTT	60	165
GAPDH	F-AGCCACATCGCTCAGACAC R-GCCCAATACGACCAAATCC	60	66

F, forward; R, reverse; AT, annealing temperature; PS, product size.

Flow cytometry

Cells were harvested at the indicated time points and stained with an Annexin V-FITC Apoptosis Detection Kit (BD Bioscience) to detect early apoptotic cells according to the manufacturer's instructions. Annexin V signals were detected by flow cytometry using a FACStar Plus Flow Cytometer (Becton-Dickinson).

MTT assay

A total of 1×10^5 hESCs per well were planted in 48-well plates in mTeSR1 and transfected with scramble or *FAM46B* siRNAs with the addition of Y-27632. Eighteen hours after transfection, medium was changed to mTeSR1. At 24, 30, 36 h after transfection, 10 μl of 5 mg ml^{-1} MTT [3-(4,5-dime-thylthiazolyl-2)-2,5-diphenyltetrazolium bromide, Sangon Bio-tech] solution was added and incubated for 4 h. DMSO (Sigma-Aldrich) was then added to solubilize the formazan product and the absorbance was measured at 570 nm.

RNA half-life analysis

H1 cells were treated with doxycycline for 12 h before incubation with 5 μg ml^{-1} actinomycin D (ActD, Sigma-Aldrich). Cells were collected at time points 0, 0.5, 1, 2, 3, 4 and 5 h after the addition of ActD. RNA was extracted using TRIzol (Sigma-Aldrich). Reverse transcription was performed with HiScript 1st Strand cDNA Synthesis Kit (Vazyme) following the manufacture's protocol. qRT-PCR was conducted with SYBR green (Bio-Rad) on an Bio-Rad

CFX96 PCR machine. The qRT-PCR data were shown as fold changes normalized to internal control GAPDH. The qRT-PCR primers not included in the qRT-PCR method section are listed as follows:

Gene	Primer sequence (5'-3')	AT (°C)	PS (bp)
Wnt5A	F-CCCTTAGGCAGGTTGGCTTT R-CACTGCAACTGAGGGGATGT	60	90
RICTOR	F-TGCAGAAGCACCCTTCACAA R-AGCCAGTTATAGCACAACCCC	60	148
SKP2	F-TGACATCGGATGCCCTCAAA R-AAGCCAAATGGCATACCACAC	60	249
PAPBC4	F-TGCAAGGTGGTGTGTGATGA R- CAGCCTCTTGGGTCTCGAAG	60	70
RPS25	F-GAAGATTCGAGGCTCCCTGG R-CTGGAGCATCTCCACCCTTG	60	128

F, forward; R, reverse; AT, annealing temperature; PS, product size.

FUNCAT assay and click chemistry

FUNCAT assay was performed as previously described (44). Briefly, 24 h after transfected with scramble or *FAM46B* siRNAs, 1×10^5 hESC cells of each sample were collected and lysed in ice-cold RIPA lysis buffer containing protease inhibitor cocktail (Sigma). HPG incorporated protein lysates were labeled selectively with Cy5-conjugated azide by copper-catalyzed azide-alkyne cycloaddition (CuAAC). Click reaction was performed following the protocol from Click Chemistry Protein Reaction Buffer Kit (Click Chemistry Tools). Finally, samples were heated at 70°C for 10 min before resolved by SDS-PAGE and imaged using a pharos FXTM Plus Molecular Imager (Bio-Rad). Loading consistency was confirmed by staining the gel with Coomassie Blue after fluorescent imaging. All experiments were repeated at least twice and the data showed satisfying consistency.

CRISPR knock-out

The inducible Cas9 *FAM46B*-knock-out hESC was generated by transfecting gRNA targeting the exons of FAM46B into the inducible Cas9 H1 cell line. Knock-out of *FAM46B* was induced by addition of 1 μg ml^{-1} doxycycline (Sigma-Aldrich), and cells were collected at different time points (0, 3, 6, 12, 24, 48 h) after doxycycline induction for analysis. The knock-out effect was of verified by qRT-PCR and Western blot using antibody against FAM46B. The gRNA sequences are 5'-AAACTATCGGCCTTCCCCGGACGGC-3' (forward) and 5'-CACCGCCGTCCGGGGAAGGCCGATA-3' (reverse).

RESULTS

Overall crystal structure of FAM46B

In order to obtain functional clues of FAM46 proteins, we solved a 2.7 Å crystal structure of nucleotide-free FAM46B protein from *Xenopus tropicalis* (xtFAM46B) with a R_{free} of 0.252 (Table 1). In the structural model, residues 1−8, 198−200 and 347−350 are missing due to disordered configuration. The protein contains an N-terminal catalytic domain (NCD, residues 9−230 resolved in the structure) and a C-terminal helical domain (HD, residues 231−346), which together form a massive cleft (Figure 1A−C). Inside the cleft, the three NTase consensus carboxylates, Asp91, Asp93 and Glu167 are present at the putative catalytic site, but we did not observe the electron density for catalytic metal ion. A conserved Arg176 directs the loop linking the two domains via hydrogen bonds and a salt bridge with Thr234, Arg235$_O$, Asn236$_O$ and Glu239 (Figure 1D). The other side of the cleft is shielded by a salt bridge between Lys90 from the NCD and Asp295 from the HD (Figure 1E). The bottom of the cleft is featured by an extensive hydrophobic network formed by residues from both NCD and HD (Figure 1F). Glu179 and Asp183 sit in the center of the cleft and interact with Lys247 protruding from the HD (Figure 1G).

The NCD is built of a central eight-stranded β-sheet (β1−β8) surrounded by seven α-helices (α1−α7) involving a typical NTase core (Figure 2A). An extended β-hairpin, composed of β$_{E1}$, β$_{E2}$ and an elongated connecting loop, is situated between α1 and α2. This FAM46-specific β-hairpin stretches vertically to the central β-sheet, and covers the valley created by α4, α5, β5 and β6 (Figure 2B). Beside the NTase core, α7 is closely associated with β1, α3, β7 and β8 via hydrophobic interactions (Figure 2C). The HD is composed of 5 α-helices. α8, α9 and α10 are packed into a triangle platform, whereas α11 and α12 form an antiparallel pair underneath (Figure 2D). The five α-helices are tightly associated via hydrophobic interactions (Figure 2E).

FAM46B is a bacterial-like PAP

The overall architecture of FAM46B does not conform to the previously calculated FAM46C model (11). Compared to other known eukaryotic PAPs such as the classical PAPα and non-classical Gld-2 or mt-PAP (45–47), the NCD of FAM46B is double-sized in terms of amino acid residue numbers, and contains more secondary elements (Supplementary Figure S1A and B). To our knowledge, FAM46 proteins are likely to bear the largest catalytic domain among all known PAPs. Compared to Gld-2, FAM46B has a substantially wider NCD and deeper cleft (Supplementary Figure S1C and D). In addition, the relative position of FAM46B NCD and HD also differs from that of the catalytic domain and central domain of Gld-2 (Supplementary Figure S1E). This somewhat 'complex' architecture of FAM46B, which is obviously distinguished from other known eukaryotic PAPs, prompted us to look for its other potential relatives in the Dali server (48). Intriguingly, FAM46B shows high topological similarity with the class-II bacterial PAPs and CCA-adding enzymes. When FAM46B is individually superimposed with *Escherichia coli* PAP I (ecPAP) (9) and *Thermotoga maritima* CCA-adding enzyme (tmCCA) (24,49), the root mean standard deviation (r.m.s.d.) values of aligned Cα atoms are 2.93 Å and 3.65 Å, respectively, although the sequence identity between FAM46B and these two prokaryotic enzymes is only ∼15% (Figure 3A and Supplementary Figure S2). In particular, the central eight-stranded β-sheet in the NCD is highly consistent with the bacterial PAPs/CCA-adding enzymes,
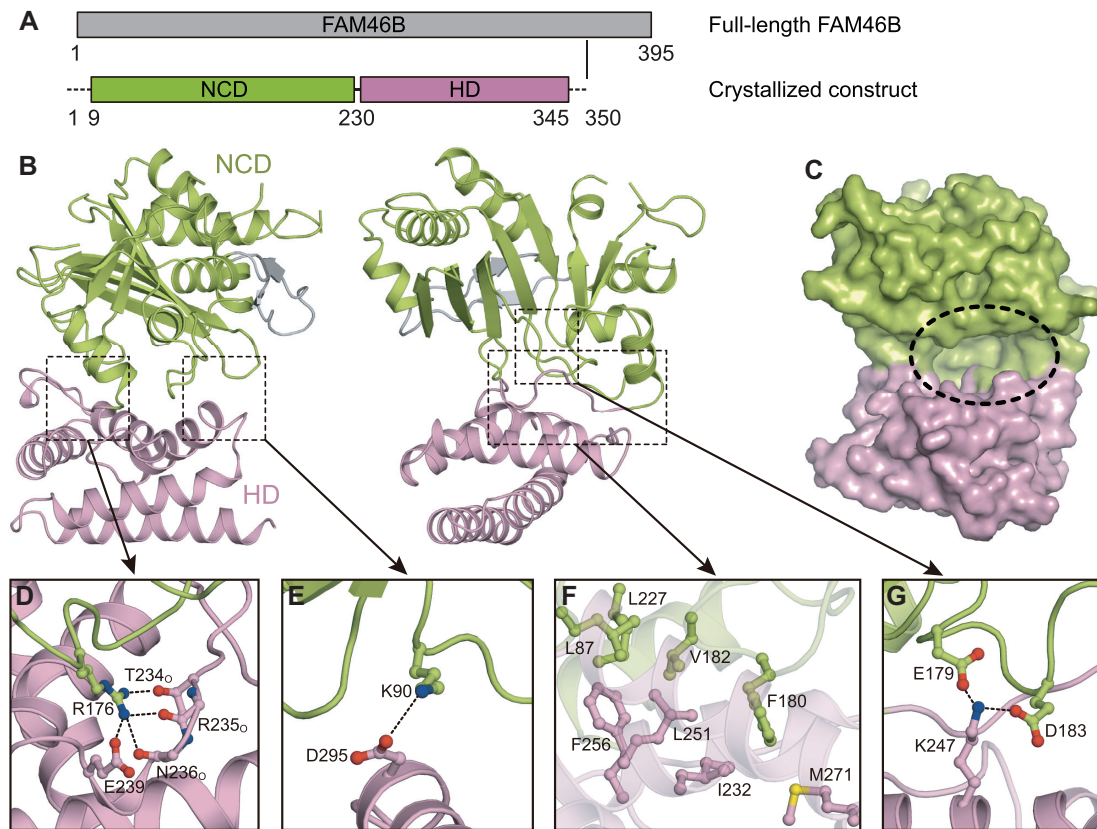

Figure 1. Overall structure of FAM46B. (**A**) Schematic representation showing the organization of crystallized construct based on full-length FAM46B. NCD, N-terminal catalytic domain; HD, helical domain. Borders of each domain are indicated by residue numbers. (**B**) Structure of FAM46B. Domains of FAM46B are indicated and colored as in A. FAM46B (magenta) is separately superimposed with ecPAP (Protein Data Bank code 3AQM, pale cyan) and tmCCA (3H39, teal). The r.m.s.d. values of aligned Cα atoms are shown. The body and tail domains of ecPAP and tmCCA are colored grey. (**B**) The topology diagram of the FAM46B NCD (top), as compared with those of the head domains of ecPAP (middle) and tmCCA (bottom), colored as in A. (**C**) The phylogenetic analysis revealing a close relationship between FAM46 proteins and bacterial PAPs. Subtypes of PAPs and CCAs are color-specified. Class I (cool colors) and II (warm colors) PAPs/CCAs are separated by a dashed line.

and the HD of FAM46B also resembles their neck domains (Figure 3A and B). The conserved inter-domain salt bridges in ecPAP and tmCCA, which are shown to be involved in the coordination of nucleotides (i.e. Asp151-Arg200 in ec-PAP, and Asp130-Arg180 in tmCCA), are equivalent to the aforementioned Glu179-Lys247 pair in FAM46B (Figure 1G and Supplementary Figure S3A). Phylogenetic analysis also revealed that compared to eukaryotic PAPs, FAM46 proteins are more closely related to class-II bacterial PAPs and CCA-adding enzymes (Figure 3C and Supplementary Figure S3B).

Following this clue, we tested whether FAM46B and FAM46C possess PAP and/or CCA-adding activities. CCA-adding enzymes catalyze the consecutive 3′-terminal CCA extension of precursor tRNAs with CTP and ATP as donors, while PAPs selectively add a string of nontemplated AMPs to the 3′-end of target mRNAs by consum-

ing ATP molecules. 5′-biotinylated 15-mer poly(A) RNA (A_{15}) and mini-tRNA substrates were individually incubated with FAM46B or FAM46C in the presence of corresponding nucleotides, and the products were visualized using streptavidin-conjugated horseradish peroxidase (HRP). Both proteins failed to add AMP or CMP to mini-tRNAs lacking 3′ A, CA and CCA (Figure 4A). On the other hand, FAM46B and FAM46C were able to elongate A_{15} in the presence of Mg^{2+}, and the lengths of the products were apparently coupled to ATP concentration (Figure 4B). When Mg^{2+} was replaced by Mn^{2+}, both proteins became more potent in catalyzing polyadenylation (Figure 4B). Notably, FAM46B showed much higher PAP activity than FAM46C, especially in Mg^{2+}-present conditions. FAM46B is able to efficiently extend oligoA substrates ranging from A_5 to A_{30}, but shows no apparent binding to AMP, ATP or ATPγS (Supplementary Figure S3C and D).
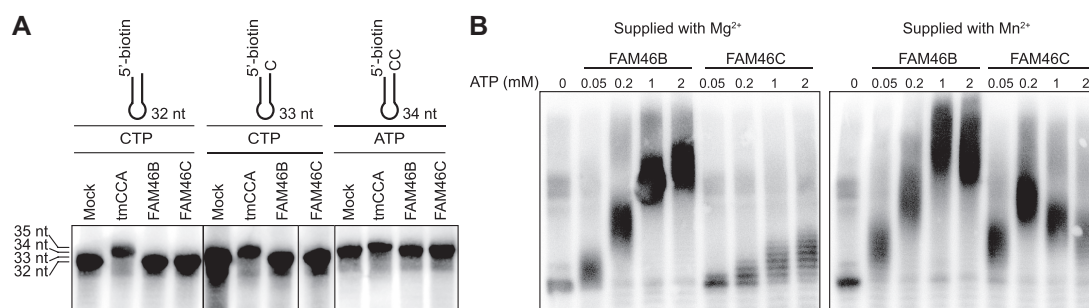

Figure 4. FAM46B has PAP activity. (**A**) Test for CCA-adding activity for human FAM46B and mouse FAM46C. 10 μM 5′-biotinylated mini-tRNA primers with different 3′ tails as indicated were individually incubated with 10 μM protein in the presence of 2 mM ATP or CTP for 50 min. tmCCA was used as a positive control. (**B**) Polyadenylation activity for human FAM46B and mouse FAM46C. 10 μM 5′-biotinylated A_{15} primer was incubated with 10 μM FAM46B or FAM46C in the presence of 4 mM Mg^{2+} or Mn^{2+} for 50 min. ATP was supplied with increasing concentrations as indicated.

tmCCA and ecPAP rely on two charged residues (Asp174 and Arg177 in tmCCA; Asp194 and Arg197 in ecPAP), which are conserved among class-II bacterial PAPs, in recognizing adenosine and cytosine nucleotides. However, structural comparison between FAM46B and tmCCA/ecPAP revealed that these two conserved residues are not present in FAM46B (Supplementary Figure S3E). Considering the lack of the nucleotide-binding affinity of FAM46B that also differs from tmCCA and ecPAP, we infer that FAM46B and FAM46C are bacterial-like poly(A) polymerases in terms of overall folding but may possess a different nucleotide binding manner from the class-II bacterial PAPs. In the rest part of the paper, human FAM46B has been used for all the experiments.

The catalytic properties of FAM46B

To investigate the catalytic properties of FAM46B, we firstly examined the nucleotide selection of FAM46B. An HPLC-based method was developed to monitor the incorporation of each monophosphate nucleotide (NMP). FAM46B and A_{15} primer were individually incubated with corresponding label-free triphosphate nucleotides (NTPs). After reaction, the mixture was applied to a C18 column with an upstream guard column to block the protein and RNA primer/product (Figure 5A). Thus, we were able to monitor the consumption of NTPs by quantifying the remaining nucleotides. When ATP was supplied, we observed decreased area of the ATP peak but no AMP peak after incubation, suggesting that ATP has been hydrolyzed and added to the A_{15} primer (Supplementary Figure S4A). In contrast, UTP, CTP or GTP was barely consumed under the same conditions (Figure 5B and Supplementary Figure S4B). Consistent with the HPLC assay, FAM46B only extends 5′-biotinylated A_{15} in the presence of ATP (Figure 5C).

In order to figure out whether FAM46B has preference on the oligonucleotide primers, we compared the ATP consumption of FAM46B in the presence of A_{15}, $A_{14}U_1$ or $U_{14}A_1$. For three cases, the remaining ATP portions were approximately 10%, 30% and 90%, respectively (Figure 5D). Similar results were observed in AMP incorporation assay using α-^{32}P-labeled ATP ([α-^{32}P]-ATP), where $A_{14}U_1$ led to less AMP incorporation than A_{15}, and $U_{14}A_1$ showed

only little ATP incorporation (Figure 5E). To further explore the potential sequence preference of FAM46B over the substrates, we used a pool of random sequences of 15 nt as primers for an *in vitro* adenosine (A)-tailing assay (Supplementary Figure S5). It turned out that FAM46B indeed prefers an AxAA sequence at 3′-end of the substrates (Figure 5F). Further experiments indicated that FAM46B extended A_{15} primer in a ATP/protein concentration-dependent manner, and the majority of poly(A) products were below 150 nt in length (Figure 5G). These results suggest that FAM46B has strong selectivity on RNA molecules that are adenosine-rich close to 3′-end, and the base type at the very 3′-end of substrate RNA also impacts polyadenylation efficiency.

The catalytic center and potential RNA-binding area of FAM46B

All NTases contain three critical motifs in the catalytic center: hG[GS], [DE]h[DE]h and h[DE]h (h indicates a hydrophobic amino acid). To verify these functional motifs in FAM46B, we mutated corresponding key residues, namely Gly107, Ser108, Asp124, Asp126 and Glu200, individually into alanine and performed AMP incorporation and ATP consumption assays (Figure 6A). Unexceptionally, these mutants failed to hydrolyze ATP in the presence of A_{15}, and lost polyadenylation activity (Figure 6B and C). We also did mutagenesis analysis for the residues involved in NCD-HD interaction (Figure 1D−G). Except for Lys123 (corresponding to Lys90 in xtFAM46B as shown in Figure 1E), mutation of other selected residues at NCD-HD interface substantially reduced PAP activity of FAM46B (Figure 6D).

Surface electrostatic potential analysis reveals that positively-charged patches exist around the catalytic center of FAM46B (Figure 6E). The mutations of patch-involving residues Lys175, Lys202, Arg209, Arg274, Lys280 and His329 to alanine all deprived the PAP activity of FAM46B. In contrast, the mutation of Arg302, an HD residue located at the opposite side of the central cleft, still remained partially active (Figure 6F). We also tested two non-charged residues close to the positively charged patches, namely Cys180 and Phe330. C180A had reduced PAP activity, and F330A was as potent as the wild type (Figure 6F). These data suggest that these positively-charged patches may be

involved in the RNA binding. Similarly, the neck domain of ecPAP also possesses a positively-charged area that has been proved critical for RNA binding (9).

FAM46B is specifically expressed during human early development

In order to get an overview of the expression profile of *FAM46* family members during mammalian early embryogenesis, we analyzed single-cell RNA-seq data of human and mouse pre-implantation embryos (50,51). *FAM46B* and *FAM46C* are maternal genes, and highly expressed in human embryos before zygotic genome activation (ZGA) (Supplementary Figure S6A). Similar transcriptional dynamics was observed also for mouse *Fam46* family during early development (Supplementary Figure S6B). Following ZGA, the transcription level of *FAM46B* and *FAM46C* is sharply decreased. Interestingly, in contrast to *Fam46b* in mouse embryos, *FAM46B* is reactivated in human blastocyst, uniquely and highly expressed in human epiblast (Supplementary Figure S6A and B). We then investigated the transcription specificity of *FAM46* members by comparing large RNA-seq datasets of multiple human embry-

onic stem cell (hESC) lines and human induced pluripotent stem cell (hiPSC) lines together with various cancer cell lines and somatic tissues (Figure 7A). The analysis showed that *FAM46B* is uniquely expressed in hESCs and hiPSCs, but not in cancer or somatic cells.

Consistent with *FAM46B* transcription in human pluripotent cells, ChIP-seq data shows that, in contrast to *FAM46A/C/D*, the promoter region of *FAM46B* is marked with transcriptionally active histone marks (H3K4me3, H3K27ac). Notably, the co-binding site of pluripotency transcription factors OCT4 and NANOG is embedded in the intron of *FAM46B*, indicating *FAM46B* transcription might directly regulated by OCT4 and NANOG (Figure 7B). These data imply a strong coupling between *FAM46B* expression and human pluripotency.

Expression of FAM46B is coupled to human pluripotency

To explore the pattern of *FAM46B* transcription during hESC differentiation, we first employed a typical spontaneous differential model: embryoid body formation. The quantitative real-time PCR (qRT-PCR) results showed that *FAM46B* expression level was gradually declined during

embryoid formation (Figure 7C). Importantly, *FAM46B* is also down-regulated in neuroectodermal and mesendormal cells differentiated from hESCs (52), indicating that *FAM46B* inactivation might be required for lineage specification and germ layer formation during the embryonic development in humans (Supplementary Figure S6C).

As FAM46B is still expressed in the early time of mesendoderm differentiation (Supplementary Figure S6C), we analyzed its transcription dynamics in detail during the mesendoderm differentiation from hESCs. We noticed that the mRNA level of *FAM46B* showed approximately 5-, 11- and 15-fold decrease at 24, 48 and 72 h after induced differentiation, respectively (Figure 7D). In contrast, the mRNA levels of *FAM46A/C/D*, as well as other known canonical and non-canonical PAPs, remained steady. Subsequent qRT-PCR analysis confirmed that the mRNA level of *FAM46B* sharply declines following mesendodermal induction (Figure 7E). In order to monitor the endogenous FAM46B protein, we knocked-in a 3 × Flag-tag to the 5′ end of *FAM46B* reading frame (Supplementary Figure S6D). Western blot analysis indicated that the FAM46B protein level decreased in a time-dependent manner upon mesendodermal induction (Figure 7F). We also examined the transcriptional dynamics of *FAM46* family during human somatic cell reprogramming (53). Intriguingly, *FAM46B* expression level is gradually increased following pluripotency acquisition, while *FAM46A* is gradually decreased, and *FAM46C/D* are not expressed during the whole reprogramming process (Supplementary Figure

S6E). Altogether, these data suggest that FAM46B is specifically expressed in human pluripotent cells and may play crucial roles in human pluripotent cells.

FAM46B is essential for the viability of hESCs

To explore the biological role of FAM46B, we tested its subcellular localization in hESCs. Immunofluorescent staining indicated a ubiquitous distribution of endogenous FAM46B (Figure 8A). Subsequent nuclear/cytosolic fractionation assay revealed a cytoplasmic preference of FAM46B residence, though it also appeared in the nuclear fraction (Figure 8B). Given the differentiation-coupled down-regulation feature of FAM46B, we investigated whether FAM46B is directly associated with pluripotency maintenance of hESCs. Knock-down of *FAM46B* by siRNAs did not significantly alter the mRNA levels of the pluripotency-related genes *OCT4, NANOG* and *SOX2* (Figure 8C and Supplementary Figure S7A and B). On the other hand, instead of causing cell differentiation, *FAM46B* knock-down severely deteriorated viability of hESCs as soon as within 30 h, as indicated by MTT assays (Figure 8D), and the growth defect was clearly observable under microscope (Supplementary Figure S7C). According to the flow cytometry analysis, apoptotic hESCs (characterized by the annexin⁺ proportion) were increased after a 24-hour treatment of *FAM46B* siRNA (Figure 8E and Supplementary Figure S7D). We also tried to knock out *FAM46B* in human embryonic cells using CRISPR/Cas9
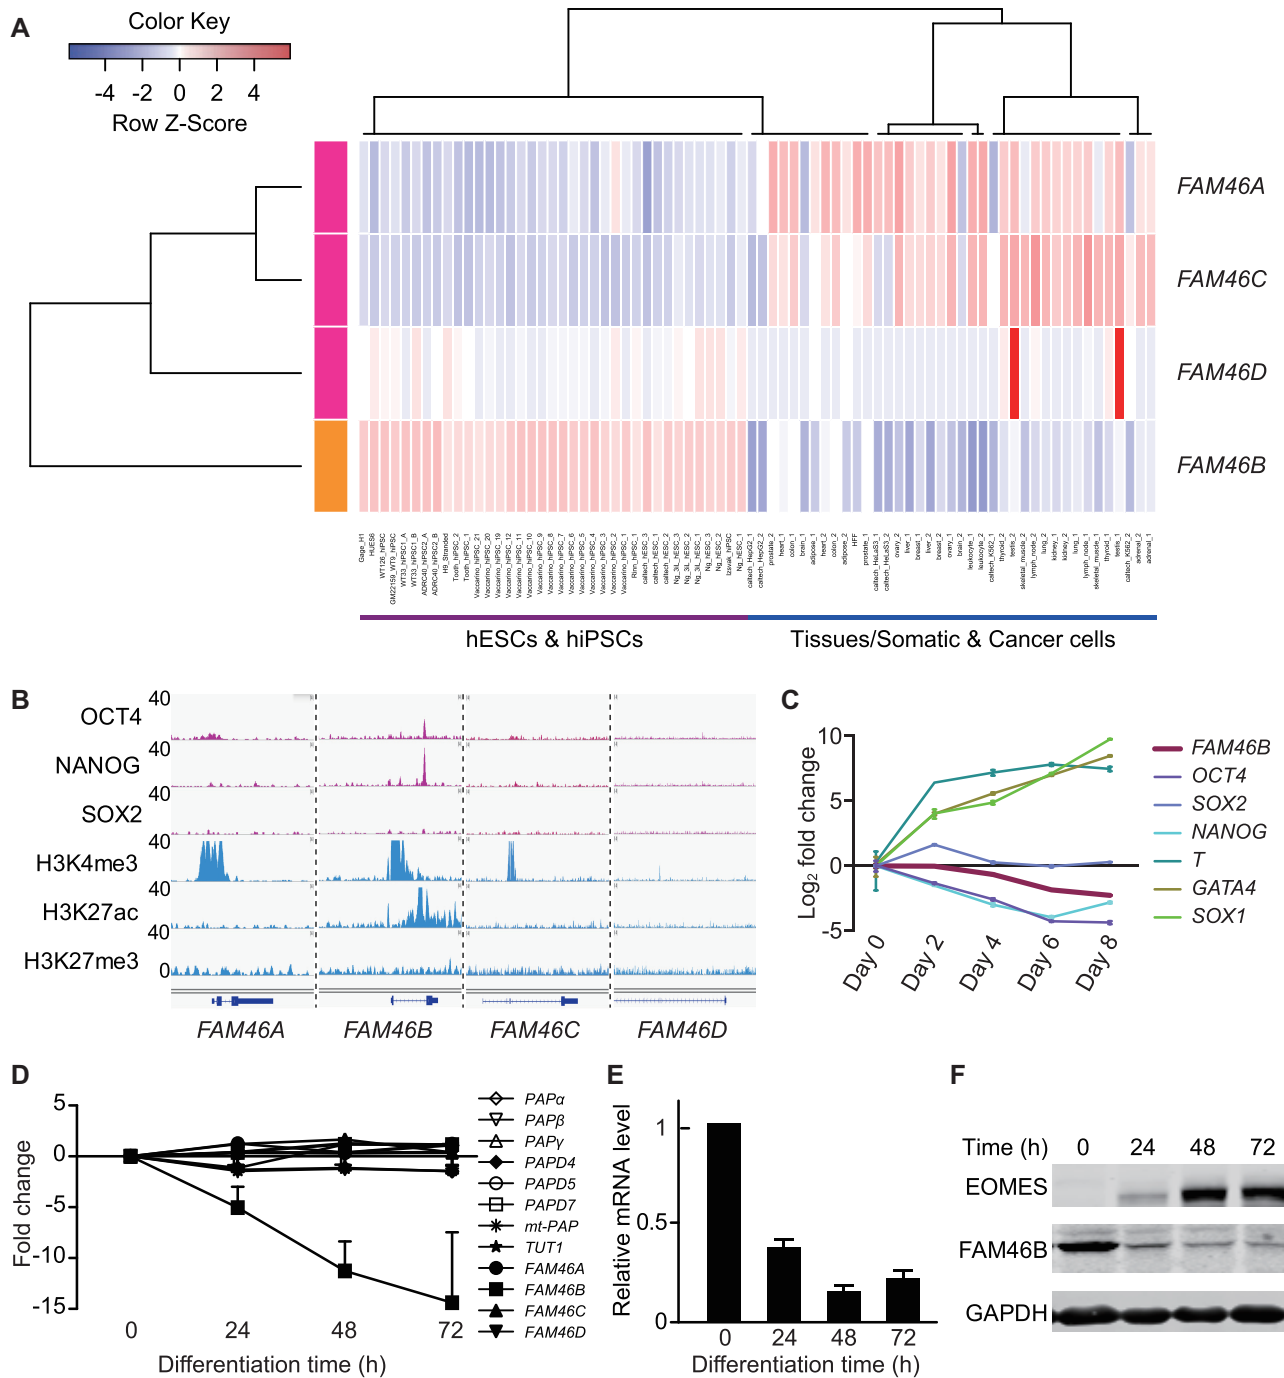

Figure 7. FAM46B is specifically expressed in human pluripotent stem cells. system. The surviving hESCs had at a least one chromosome copy intact, while perished hESCs had frame-shift insertions or deletions (data not shown) on *FAM46B* induced by Cas9 for both chromosome copies. These results suggest that FAM46B may not be directly involved in pluripotency maintenance, but is essential for the viability of hESCs.

To understand how FAM46B affects the viability of hESCs, we checked whether FAM46B plays a role in protein synthesis by using the fluorescent non-canonical amino acid labeling (FUNCAT) strategy (Supplementary Figure S8). In order to avoid severe cell death, hESCs had to be collected at 24 h after transfection of siRNAs. Newly synthesized proteins were labeled using homopropargylglycine (HPG) and detected via click chemistry. When FAM46B was knocked-down, the amount of newly synthesized proteins in hESCs was somewhat declined (Supplementary Figure S8B). We measured mRNA half-life of 8 selected

genes, which are functionally linked with FAM46 proteins or mediate pluripotency, in *FAM46B* conditional knock-out hESCs. Within 5 h of treatment of actinomycin D, mRNA levels of *Wnt5A*, *NANOG*, *FAM46B*, *RICTOR* and *SKP2* were substantially declined, whereas those of other genes remained relatively steady (Figure 8F, Supplementary Figure S8C). These data indicate that FAM46B may be involved in maintaining the translation efficiency of at least some genes in hESCs through preventing degradation of their mRNAs (Figure 8G).

DISCUSSION

In this study, we have identified FAM46B as a novel type of eukaryotic non-classical PAP. The striking structural similarity with bacterial PAP distinguishes FAM46B from other known eukaryotic PAPs. Consistently, FAM46B also shares

similar functional properties with its bacterial relatives but not eukaryotic non-classical PAPs, as proven by our biochemical analysis. First, like bacterial PAPs, FAM46B actively catalyzes polyadenylation without extra partners *in vitro*. For eukaryotic ceGld-2, a partner (ceGld-3) is indispensable for its enzymatic efficiency, as ceGld-3 promotes the stability of ceGld-2 by sheltering a hydrophobic area on its surface, and provides extra interface for binding the RNA substrate (46). While FAM46B has no prominent hydrophobic area on the surface, and its large NCD contains plenty of potential RNA binding sites, a Gld-3-like partner thus seems unnecessary for FAM46B. Second, although favoring A-rich over U-rich sequence, FAM46B lacks strict discrimination on RNA substrates at least *in vitro*. This is also a feature inherited from bacterial PAP (8).

These bacterial-like features of FAM46B provide valuable clues for explaining the biological role of FAM46B. The early embryos of metazoans are transcriptionally inactive, which entails robust cytoplasmic polyadenylation to stabilize the mRNAs and increase translational efficiency (19,20). Except for FAM46B reported in this study, only a couple of eukaryotic cytoplasmic PAP have been identified and characterized, such as Gld-2 (4). While Gld-2 is essential in *C. elegans*, *Drosophila* and *Xenopus*, knock-out of this PAP shows no visible phenotype in mice (54). This evidence implies that, other PAPs functionally overlapping Gld-2 are likely to exist in mammals. Given the fact that FAM46B is an active PAP with endogenously cytoplasmic localization and unique and dynamic expression profile in human pre-implantation embryos and hESCs/hiPSCs, it is tempting to speculate that FAM46B is involved in cytoplasmic polyadenylation of mRNA in the early stage of human embryogenesis. Interestingly, FAM46B and FAM46C have been found to be essential for the meiosis in mammalian oocytes (55). Re-analysis of single-cell RNA-seq datasets of human germline and embryonic development covering stages from primordial germ cells (PGCs) to hatched blastocyst indicates that the mRNA levels of *FAM46B* and *FAM46C* dramatically increase in PGCs and the zygote stage of early development, till ZGA initiation (50,56). These studies imply that FAM46B and/or FAM46C may function as early as during gametogenesis. According to our results, FAM46B is most likely involved in the overall translational control of the hESCs without significantly altering the transcriptional profile. Given its potent PAP activity, a reasonable speculation is that FAM46B may counterbalance the deadenylation of mRNAs to maintain the poly(A) tail length of mRNAs at a steady level (14,15), so as to ensure the translational efficiency. Understanding the detailed mechanism on how FAM46B influence translation in hESCs required future studies based on transcriptome-wide characterization of mRNA poly(A) tail-lengths and quantitative proteomics.

The prominent negative correlation between expression level and cell differentiation suggests that FAM46B is not all-time needed during the embryonic development. The mRNA level of FAM46B in *Xenopus* shows high consistency: it grows steadily from two-cell stage until blastula stage and then sharply dives to almost zero (57). Thus, it is possible that FAM46B also functions in non-mammals. On the other hand, functions of Gld-2 are mostly described

in gametogenesis (21–23), and its mRNA level remains unchanged after hESC differentiation. FAM46B and Gld-2 may account for cytoplasmic polyadenylation in different situations of early animal development. This arouses interesting questions: why the animal embryos require a bacterial-like PAP before they run into complexity? To answer this question, future studies are demanded to reveal the exact RNA substrates and putative regulatory factors of FAM46B, for which many possibilities need to be considered. For instance, some non-classical PAPs are found to catalyze the addition of single nucleotide to microRNAs (58), or require non-protein partners (59). In addition, it might be worthwhile to seek the connections between early animal embryos and bacteria in the control of poly(A) tail length. In contrary to eukaryotes, polyadenylation in bacteria usually leads to the degradation of regulatory RNAs and eventually causes translation inhibition (8). In this context, the observation that hESCs are extraordinarily sensitive to FAM46B depletion is somewhat analogous to the situation in bacteria: even moderate overexpression of PAP I is lethal to *E. coli* (60).

The crystal structure of FAM46B provides important clues in the future research of FAM46 proteins. Cytoplasmic polyadenylation is suggested to be active in early animal embryos and neuronal synapses (18). Coincidently, existing evidence of FAM46 proteins reveals its relationship with development and neuronal disorders. It has been reported that FAM46A is expressed in tooth germs and may be involved in the formation of tooth enamel (61). Mutations in FAM46A are found responsible for several autosomal recessive disorders in humans, including osteogenesis imperfecta and retinitis pigmentosa (62–64). Overexpression of FAM46D is closely associated with autism spectrum disorder-like behaviors in a mouse model (65). Human FAM46B shows 55%, 55% and 43% sequence identity to human FAM46A, FAM46C and FAM46D, respectively, which implies that these FAM46 proteins would share extensive structural and biochemical similarity to FAM46B. Thus, the feature as bacterial-like PAPs is the key to understand the functional mechanisms of FAM46 proteins in their various biological roles.

DATA AVAILABILITY

The X-ray crystallographic coordinates and structure factor files for xtFAM46B structure have been deposited in the Protein Data Bank (PDB) under the accession number 6JYJ.

SUPPLEMENTARY DATA

Supplementary Data are available at NAR Online.

ACKNOWLEDGEMENTS
